The Vortex of Burgers in Protoplanetary Disc

Martin G. Abrahamyan
Department of Physics, Yerevan State University, Yerevan, Armenia; martin.abrahamyan@ysu.am

Abstract. The effect of a Burgers vortex on formation of planetesimals in a protoplanetary disc in local approach is considered. It is shown that there is not any circular orbit for rigid particles in centrifugal balance; only stable position in Burgers vortex under the influence of centrifugal, Coriolis, pressure gradient and Stokes drag forces is the center of vortex. The two-dimensional anticyclonic Burgers vortex with homogeneously rotating kernel and a converging radial stream of substance can effectively accumulate in its nuclear area the meter-sized rigid particles of total mass $\sim 10^{28}$ g for characteristic time $\sim 10^6$ yr.

1. Introduction

The radial dependence of infra-red, sub mm and cm radiation of protoplanetary disks analyses show that vortices serve as incubators for growth dust particles and formation of planetesimals (Heng & Kenyon 2010). Formation of planetesimals from micron size dust grains possibly, involves many physical processes (Youdin 2010). It is accepted that growth of particles in dusty circumstellar discs is hierarchical (Armitage 2007, 2010). The initial stage of growth probably proceeds through the nucleation of submicron-sized dust grains from the primordial nebula, which then forms the monomers of fractal dust aggregates up to $\sim 1$ mm to $\sim 10$ cm for characteristic time of an order of $10^3$ years. The further growth of particles by this mechanism is stopped by collisional destruction process (Blum & Wurm 2008; Zsom et al. 2010). In this stage the dynamics of particles and coagulation are regulated by van der Waals forces and the Brownian motion. The best astrophysical evidence for grain growth to specified sizes is the detection of 3.5 cm dust emission from the face-on disk of radius 225 AU round classical T Tauri star TW Hya (age $\sim 5$–10 Myr), located 56 pc away (Wilner et al. 2005). When the planetesimals reached a size of about 1 km, they began to attract other smaller bodies due to their gravity.

In standard models of protoplanetary disks, gas pressure decreases along radius. Gas in a disk practically moves on sub-Keplerian speeds. Rigid particles, under the action of a head wind drags, lose the angular momentum and energy. As a result, the $\sim 10$ cm to meter-sized particles drift to the central star for hundreds of years, that is, much less than the lifetime of a disk which makes several millions of years (Adachi et al. 1976; Weidenschilling 1977).

Long-lived vortical structures in gas disk are a possible way to concentrate the $\sim 10$ cm to meter sized particles and to grow up them in planetesimal. Similar effect of vortices on the Earth observed in special laboratories, and also in the ocean. For
example, the oceanic vortices trap larval fish off the coast of Western Australia (Paty et al. 2008).

In some areas of the stratified protoplanetary disks the current has 2D-turbulent character. An attractive feature of such hydrodynamic current consists in the fact that in it, through a background of small whirlpools, long-living vortices will spontaneously be formed without requirement of special initial conditions (Carnevale et al. 1991; Weiss & McWilliams 1993; Tabeling 2002). In laboratory experiments (Lazaro & Lasheras 1992), formation of Burgers vortex which will be considered in the present work is often observed in 2D-turbulent flows. If protoplanetary disks are capable of producing 2D-turbulent flow, they can form long-living large-scale vortices which in due course lives up to an order of hundred orbital periods. Anticyclonic vortices in a protoplanetary disk merge with each other and amplify, while cyclonic ones are destroyed by a shear flow.

In an anticyclone, rigid particles are grasped by force of Coriolis directed to the center of a vortex. If the vortex survives ~100 rotations in a nebulae with solar mass, the quantity of the grasped particles can reach masses of planets (several masses of the Earth). Existence of long-living vortices in the protoplanetary disk, drifting of external regions of a disk, allows accumulation of the mass necessary for formation of a kernel of a giant planet (Inaba et al. 2005; Inaba & Barge 2006).

Figure 1. Rotational velocity profiles of Burgers and Rankin vortices.

In the present work the Burgers vortex in a protoplanetary disc and its role in a problem of formation of planetesimals will be considered. The vortex of Burgers in cylindrical system of co-ordinates \((r, \Theta, z)\) is defined as

\[
V_r = -A_r, V_\Theta = \omega r_0^2 \left[1 - \exp(-r^2/r_0^2)\right]/r, V_z = 2Az
\]

This represents a vortex with a converging stream of substance to its center where \(A\) characterizes a converging stream, and \(\omega\) and \(r_0\) - circulation and the size of a trunk of a vortex. Rotation in the field of a vortex trunk is almost rigid-state and on the big distances a profile of rotational speed falls down under the hyperbolic law (Fig. 1). The asymptotic behavior of Burgers vortex in small and big distances from the vortex center represents the Rankin vortex (Abrahanyan 2008; Abrahanyan & Matveenko 2012). The maximum rotational speed in Burgers vortex is equal \(0.638 \omega r_0\) which is reached at \(r/r_0=1.121\). At distance \(r_{eff} = 4.5r_0\), rotational speed makes one-third of the maximum value. Conditionally we will name this distance “effective radius” of Burgers vortex.
2. The Magnitude of Some Parameters of a Disk

We consider the Burgers vortex in viscous axially-symmetrical accretion disk with effective temperature $T$, gas volume density $\rho$, of almost Keplerian rotation. The sound speed in gas is estimated by the formula

$$c_s = \sqrt{\gamma kT/m_H} \approx (\gamma T/100K)^{1/2} \text{km/s}$$  \hspace{1cm} (2)

where $\gamma = 1.4$ the gas adiabatic index, $k$ - Boltzmann constant, $m_H$ - hydrogen atom mass.

In a vertical direction, the gas is in hydrostatic balance with a characteristic scale height

$$H \sim \frac{c_s}{\Omega} \approx 0.03 \left[ \frac{T}{100K} \right]^{1/2} \left[ \frac{M_*}{M} \right]^{1/2} \left[ \frac{R}{AU} \right]^{3/2} \text{AU}. $$  \hspace{1cm} (3)

The superficial density of the gas in a disk can be estimated as $\Sigma \approx 2H \rho$.

In $\alpha$ - model of accretion disk (Shakura & Sunyaev 1973), the expense of gas occurs with a speed $dm/dt = 3\pi \nu \Sigma$, where $\nu$ - kinematic viscosity of gas $- \nu = \alpha c_s H$.

The characteristic dynamic time scale of a disk is:

$$\tau \sim \frac{1}{\Omega} \approx \frac{1}{5} \left[ \frac{M_*}{M} \right]^{1/2} \left[ \frac{R}{AU} \right]^{3/2} \text{yr}. $$  \hspace{1cm} (4)

For Keplerian disk, radial momentum equation solution yields to a difference between the speeds of rigid particles and surrounding gas (Pringle 1981). In a thin gas disk ($c_s \ll \Omega R$), rigid particles drift relative to gas with a speed

$$\frac{\Delta \nu}{c_s} \sim \frac{c_s}{\Omega R} \approx 0.03 \left[ \frac{T}{100K} \right]^{1/2} \left[ \frac{M_*}{M} \right]^{1/2} \left[ \frac{R}{AU} \right]^{1/2} \text{AU} $$  \hspace{1cm} (5)

At $c_s \sim 1 \text{ km/s}$, typical drift speed is of order 30 m/s. The characteristic scale of drift time (Adachi et al. 1976; Weidenschilling 1977) almost by two orders surpasses dynamic time $\tau$

$$\tau_d \sim r/\Delta \nu \sim (R/AU) 10^2 \text{yr}. $$  \hspace{1cm} (6)

Dust settled on a midplane of a disk for a characteristic time (Chiang & Goldreich 1997) and characteristic time between collisions of rigid particles among themselves are estimated as

$$\tau_s \sim \Sigma/\alpha \Omega \rho^* \text{ and } \tau_{col} \sim D \rho^*/\Sigma^* \Omega,$$  \hspace{1cm} (7)

where $\rho^*$ is the mass density of a particle, $D$ is the diameter of a particle, $\Sigma^*$ is the superficial density of rigid particles in a disk which is more than by two orders less than a disk $\Sigma$. For metre-size rigid particles, this time is of an order of $\sim 5\text{yr}$. Therefore for creation of rigid particles with the sizes significantly surpassing the meter size, it is necessary to provide an environment with high concentration of particles in rather small regions. Such environment is provided by vortices.

Particles in a vortex are exposed to actions of centrifugal, Coriolis, drag forces, and in a smaller measure, to gradient forces of pressure. If centrifugal force deletes a particle from the vortex centre, drag and Coriolis forces in an anticyclonic Burgers
vortex are directed to its centre. Acceleration of a rigid particle is directed to the vortex centre if the vortex angular speed \( \omega = |\delta \theta / \delta t| \) at a small friction is less than \( 2\Omega \),

\[
\omega < 2\Omega,
\]

– a condition which is always carried out in practice.

Viscous dissipation and orbital shear limit the sizes of a vortex. Viscous dissipation destroys vortices of sizes less than viscous scale (Inaba & Barge 2006)

\[
L_\nu = \frac{\alpha c_s H}{\nu_\theta} \approx 0.003 \left[ \frac{\alpha}{0.01} \right] \left[ \frac{0.1c_s}{\nu_\theta} \right] \left[ \frac{M_*}{M} \right]^{1/2} \left[ \frac{R}{AU} \right]^{3/2} AU,
\]

where \( \nu_\theta \) – rotational speed of a vortex.

The Keplerian shear flow forbids formation of circular structures with the sizes larger than shear length scale (Godon & Livio 2000),

\[
L_{\text{shear}} \sqrt{\nu_\theta \left[ \frac{d\Omega}{dR} \right]^{-1}} \approx 0.05 \left[ \frac{\nu_\theta}{0.01c_s} \right]^{1/2} \left[ \frac{M_*}{M} \right]^{1/4} \left[ \frac{R}{AU} \right]^{5/4} AU.
\]

The vortices, whose sizes surpass \( L_{\text{shear}} \), are extended in an azimuthal direction that allows them to survive longer. In (Abrahmyan 2016) we have shown the possibility of formation in a disk extended in an azimuthal direction three-axis ellipsoidal vortex, with a linear field of circulation, similar to Riemann S ellipsoids (Chandrasekhar 1969). However, note that in a disk round the central star of solar mass, at distance 30 AU, the vortex of characteristic speed of rotation 0.01\( c_s \), can be circular and have the size of an order ~ 1AU.

In a gas disk, drag force on rigid particles from gas is exposed, which, depending on size of a particle, is expressed either by Stokes, or Epstein’s formula (see, for example, Inaba et al. (2005). If the sizes \( D \) particles are small in comparison with gas mean free path, such particles are exposed to the Epstein drag force:

\[
F = \frac{\rho c_s}{\rho^* D} \Sigma^*(v - u),
\]

where \( v \) – velocity of gas, \( u \) - velocity of rigid particle. Particles of the big sizes are exposed to the Stokes drag force (see (15)).

3. The Burgers Vortex in Local Frame of Reference

Let’s use local approach, choosing frame of reference, rotating with a disk with angular speed \( \Omega_0 \) at distance \( R_0 \) round the central star of mass \( M \). In this approach, assuming the sizes of a vortex are much smaller than the distance \( R_0 \), we will choose Cartesian system of co-ordinates with center \( O \) (Fig. 2), directing the \( Y \) axis to a star, and the \( X \) axis in direction of Keplerian flow of gas. We will present the disk rotation as \( \Omega(R) \propto R^{-q} \). In case when only the gravitation of the central star operates, rotation will be Keplerian with \( q = 3/2 \), and for homogeneously rotating disk \( q = 2 \), i.e. \( 2 \geq q \geq 3/2 \).

In the chosen system of reference, the substance stream has \( X \) component of speed \( -iq\Omega_0 y \), centrifugal force is compensated by radial component of gravitation of the central star at distance \( R_0 \), in other points their sum gives the tidal force \( j\Omega_0 y z \). The vertical component of gravitation \( -\Omega_0^2 z \) is returning force along axis \( Z \).
At first we will consider a gas disk round the central body. In local approach, the equation stationary isentropic shear flow of gas taking into account viscosity will be described by Navier-Stokes and continuity equations

\[(v \nabla)v = j3\Omega_0^2 y - k\Omega_0^2 y - 2\Omega_0^2 \times v - \nabla h + v\Delta v\]  \hspace{1cm} (12)

\[\nabla(\rho v) = 0,\]  \hspace{1cm} (13)

where \(h\) - specific enthalpy \((h = \int \rho^{-1} dp)\), \(i, j\) and \(k\) - Cartesian ors. The first term in the right side of equation (12) is, as noted above, tidal acceleration in a plane of the disk, the second term is vertical component of gravitation, the third is acceleration of Coriolis, the last is a viscous stress.

In the chosen Cartesian co-ordinate system the Burgers vortex will be presented in the form

\[V_x = -Ax - \omega r_0^2 y\left[1 - \exp(-r^2/r_0^2)/r^2\right], \quad V_y = -Ay - \omega r_0^2 x\left[1 - \exp(-r^2/r_0^2)/r^2\right], \quad V_z = 2Az,\]  \hspace{1cm} (14)

where \(r^2 = x^2 + y^2\).

It is easy to check that solutions (14) satisfy to the continuity equation at \(d\rho/dt = 0\) – that is comprehensible in local approach. Substituting (14) in the equation (12), we will receive expression for specific enthalpy \(h(x,y,z)\). However we will not present the bulky expression for \(h(x,y,z)\). We will only describe spatial profiles of gradient forces \(\delta h/\delta x\) and \(\delta h/\delta y\) in \(X,Y\) plane in anticyclonic Burgers vortex (fig. 3).

4. The Dynamics of Rigid Particles in Burgers Vortex

In the present work, we will be limited to studying two-dimensional dynamics of dust rigid particles in a Burgers vortex taking into account action pressure gradient force \(\nabla h\), tidal force, forces of Coriolis and a friction. Thus we will neglect the influence of rigid particles on dynamics of gas, and also the interaction of rigid particles among themselves.

Let’s consider that the sizes of particles \(D\) considerably surpass the mean free path of molecules of gas, therefore we will describe the friction of rigid particles with gas by Stokes drag force.
\[ f = \beta(v - u), \]  
(15)

where
\[ \beta = 18 \rho v / \rho^* D^2, \]  
(16)

\( u \) - velocity of a particle:
\[ u = (dX/dt, dY/dt), \]  
(17)

X, Y - particle co-ordinates.

The equation of motion of dust particles in the accepted approach looks like:
\[ du_x/dt = 2\Omega_0 u_y - \beta(v_{x||r=(x,y)} - u_x) \delta h / \delta x_{||r=(x,y)}, \]  
(18)

\[ du_y/dt = 3\Omega_0^2 y - 2\Omega_0 u_x - \beta(v_{x||r=(x,y)} - u_x) \delta h / \delta y_{||r=(x,y)}. \]  
(19)

It is convenient to present these equations in a dimensionless form. As characteristic length of a problem we will accept the size of a trunk of a vortex \( r_0 \), for characteristic time and speed - 1/\( \Omega_0 \) and \( \Omega_0 r_0 \) respectively. Then the equations (18), (19) will become
\[ du_x/dt = 2u_y + \gamma (v_{x||r=(x,y)} - u_x) \delta h / \delta x_{||r=(x,y)}, \]  
(20)

\[ du_y/dt = 3y - 2u_x + \gamma (v_{y||r=(x,y)} - u_y) \delta h / \delta y_{||r=(x,y)}, \]  
(21)

where \( \gamma \) - dimensionless parameter
\[ \gamma = \beta / \Omega_0 = 18 \rho v / \rho^* D^2 \Omega_0. \]  
(22)

Let’s consider at first the dynamics of particles in the vortex trunk \( (r^2 / r_0^2 < 1) \) where the profile of rotation of a vortex has uniform character. In a dimensionless form
\[ V_x = -Ax - \omega y + O(r^2 / r_0^2), \quad V_y = -Ay + \omega x + O(r^2 / r_0^2), \]  
(23)

where A and \( \omega \) are measured in units \( \Omega_0 \). From (2) taking into account (13) it is found
\[ \delta h / \delta x = -(A^2 - \omega^2 - 2\omega) x - 2A(\omega + 1)y, \]  
(24)

\[ \delta h / \delta y = 2A(\omega + 1)x - (3 + A^2 - \omega^2 - 2\omega)y. \]  
(25)
Substituting (23) - (25) in the equations (20) and (21), we will receive the equations of motion of rigid particles in the field of a vortex trunk:

\[
\begin{bmatrix}
\dot{X} \\
\dot{Y} \\
\dot{u}_x \\
\dot{u}_y
\end{bmatrix} =
\begin{bmatrix}
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1 \\
a & b & -\gamma & 2 \\
-b & a & -2 & -\gamma
\end{bmatrix}
\begin{bmatrix}
X \\
Y \\
u_x \\
u_y
\end{bmatrix}
\]

(26)

where

\[a = A(A - \gamma) - (\omega + 1)^2 + 1; b = 2A(\omega + 1) - \gamma\omega.\]  

(27)

From these equations it is visible that equilibrium position of rigid particles in a vortex trunk is its centre \(X = Y = 0\), where \(u_x = u_y = 0\) and \(\dot{u}_x = \dot{u}_y = 0\). Particles in considered area gradually come nearer to the centre of the vortex by helicoidal trajectories.

For establishing the stability of this position of balance, it is necessary to require real parts of eigenvalues of a matrix (26) to be zero or negative.

The matrix of factors (26) has complex eigenvalues of a kind

\[
\Lambda_{1,2,3,4} = -\gamma/2 \mp i \pm \sqrt{a - 1 + \gamma^2/4 \pm (b - \gamma)},
\]

(28)

After allocation of real part of (28), for stability we receive a condition

\[\pm (b - \gamma)^2 + \gamma^2(a - 1) \leq 0,\]

(29)

at which centrifugal force is always less than the sum of drag and Coriolis forces, and the resultant force operating on a rigid particle, is directed to the vortex centre.

From (29) the necessary condition of stability follows: \(a \leq 1\), which taking into account (27), gives \((\omega + 1)^2 > A(A - \gamma)\) that is satisfied for any positive values of \(A\) and \(\gamma\). The condition (29) with the account (27) leads to stability criterion

\[\gamma < A,\]

(30)

that taking into account (16), in a dimensional form, for viscosity \(\nu\) gives

\[\nu > \rho^*AD^2/18\rho\]

(31)

Consider now the question whether there exists an anticyclonic orbit in the volume of Burgers vortex (1) on which the sum of Coriolis and drag forces is counterbalanced by centrifugal force, i.e. in local cylindrical system of co-ordinates

\[
\gamma Ar + 2u_\theta = u_\theta^2/r, \quad \text{or} \quad (u_\theta/r)^2 - \gamma A = 0.
\]

It represents the transcendental equation which in a dimensional form looks like

\[
[1 - \exp(-r^2/r_0^2)]r_0^2/r^2 = B, \quad \text{where} \quad B = [1 + \sqrt{(1 + \beta A/\Omega_0^2)}]\Omega_0/\omega.
\]

(32)

The equation (32) has real solutions for orbit radius only at \(B \leq 1\) (fig. 4), and \(r = 0\) at \(B = 1\). From expression \(B\) it is visible that \(B > 2\Omega_0/\omega\). This condition leads to the result \(B > 1\). Hence, unique position of balance for rigid particles in a Burgers vortex is
its centre where all particles captured by a vortex will gather during the characteristic time

$$\tau \sim \omega r_{\text{eff}} \sqrt{\beta \nu}.$$  \hspace{1cm} (33)

The mass of the rigid particles captured by a vortex is an order

$$M_p = \pi r_{\text{eff}}^2 \Sigma^*,$$  \hspace{1cm} (34)

which forms a planetesimal.

5. The thickness of disk in nuclear area Burgers vortex

So far we have considered behaviour of a whirlwind in a disk plane. However the whirlwind of Burgers is 3D formation. We will discuss now a question on a thickness of a disk in the area where the whirlwind of Burgers is located. For this purpose we will address to a $z$-projection of the Navier - Stokes equation (12). Integrating this equation taking into account the formula for speed $v_z$, we will receive dependence enthalpy from $z$ co-ordinate:

$$h(z) = c_{s0}^2 - (4A^2 + \Omega_0^2)z^2/2,$$  \hspace{1cm} (35)

Where $c_{s0}$ is a sound speed at the vortex centre (enthalpy, $h_0 = c_{s0}^2$, at the center of vortex is estimated by Clapeyron equation), $\Omega_0$ is angular speed of rotation of local frame of reference. Whence we obtain half-thickness of a disk at the kernel area of a whirlwind:

$$z_0 = c_{s0} / \sqrt{(2A^2 + \Omega_0^2/2)}.$$  \hspace{1cm} (36)

The thickness of Keplerian disk turns out from a condition of hydrostatic equilibrium of gas, and is defined by the formula (3). The question arises, whether changed the disc thickness in area of vortex localization?

On radius of $R_0$ the half-thickness of Keplerian disk is equal

$$z_K \equiv c_{s0}/2\Omega_0.$$  \hspace{1cm} (37)
Relative thickening,

\[
\frac{\Delta z}{z_K} \equiv \frac{z_0}{z_K} - 1 = \frac{2 \sqrt{2}}{\sqrt{(1 + 4A^2/\Omega_0^2)}} - 1,
\]

is positive if

\[ A < 1.3\Omega_0. \tag{39} \]

This condition is carried out in all areas of a typical protoplanetary disk. So the disc in the area of localization of a whirlwind of Burgers, is thicker.

6. Discussion

Let’s estimate an order of magnitudes \( \tau \) and \( M_p \) for a model of a disk of radius 30AU and mass 0.5 \( M_\odot \) round a star of solar mass: \( M \approx M_\odot \), also we will place the local frame of reference at distance \( R_0 = 20 \) AU. This gives estimations \( \Omega_0 \approx 8\Delta 10^{-9}s^{-1} \) and \( \Sigma \approx 1600g/cm^2 \).

For a typical protoplanetary disk at distance \( R_0 = 20AU \). The vertical scale height is of order \( H \approx 10^8 \) km. For sound speed, then, we receive an estimation \( c_s \approx H\Omega_0 \approx 0.8\) km/s.

Choosing different values for vortex parametres, it is possible to receive different results. For example, accepting the maximum speed of rotation of a vortex \( 0.01 \) km/s at distance \( r_0 \approx 10^7 \) km from its center, and speed of a converging stream \( v_r = A \cdot r_0 \approx 0.005 \) km/s, we will receive

\[ \omega \approx 10^{-9}s^{-1}, A \approx 5 \cdot 10^{-10}s^{-1}. \tag{40} \]

The condition of stability of position of rigid particles in the center of a Burgers vortex for viscosity (31) is carried out with a large supply for protoplanetary disks. The matter is that the molecular viscosity of gas, estimated by the formula \( \nu \sim \lambda c_s \), in which \( \lambda \) is the mean free path of molecules, \( c_s \) is the speed of a sound, does not play an appreciable role in processes of a protoplanetary disk. Really, the mean free path is defined as \( \lambda \sim 1/n\sigma \), where \( n \) is the concentration of molecules of gas, \( \sigma \) is the section of their interaction. Concentration of molecules is equal in the central plane of a disk to \( n \sim \Sigma/(2m_H H) \approx 10^{14}cm^{-3} \). Taking interaction section close to the area of a molecule of hydrogen \( (\sigma \sim 10^{-16}cm^2) \), we will receive: \( \lambda \sim 20 \) cm, \( v \sim 10^6cm^2/s \). Characteristic time of evolution of the disk is of the order of \( \tau = R^2/\nu \), that makes \( \sim 10^{13} \) yrs, which is 10^6 times more than the observable time of disk evolution.

For this reason, the ‘\( \alpha \)-disk’ (Shakura & Sunyaev 1973) model is used to describe accretion disks, in which turbulent viscosity is represented by the expression \( v \sim \alpha c_s H \approx \alpha H^2\Omega_0 \), the dimensionless parameter \( \alpha \) is considered as constant value of an order \( \alpha \approx 10^{-2} \). The scale of viscous length thus makes \( L_v \approx 10^6 \) km, so Burgers vortex of big sizes cannot be destroyed by viscosity. Keplerian shear length makes \( L_{\text{shear}} \approx 6 \cdot 10^9 \) km. Hence, vortices with the sizes \( r_{eff} \leq L_{\text{shear}} \) can have circular form.

Taking into account that \( \rho^* / \rho \approx 10^{10} \) in a midplane of a disk, using in (33) also the average value for viscosity from stability condition (31), we will receive the following estimations:

\[ M_p \approx 10^{28}g; \quad \tau \approx 3 \cdot 10^6(m/D)\text{yrs} \tag{41} \]
The Vortex of Burgers in Protoplanetary Disc

So, during an order of $\sim 10^6$ yrs, for meter-sized rigid particles, in the vortex trunk the mass amount comparable with mass of Venus accumulates.

7. Conclusion

From stated above it follows that the formation of planetesimals by means of an anticyclonic Burgers vortex is effective enough. Operating on rigid particle in such a vortex force of Coriolis, Stokes drag force and pressure gradient force are directed to its center. There is not any circular orbit in centrifugal balance in Burgers vortex in local approach. Only stable position for rigid particle is the vortex center.

Our estimations for a typical protoplanetary disc show that the two-dimensional anticyclonic Burgers vortex with homogenously rotating kernel and a converging radial stream of substance can effectively accumulate in its nuclear area meter-sized rigid particles of total mass $\sim 10^{28}$ g (or more) for characteristic time $\sim 10^6$ yr.
